

Model Selection with Transaction Costs*

Andrew Detzel[†] Robert Novy-Marx[‡] Mihail Velikov[§]

[PRELIMINARY, CLICK HERE FOR LATEST VERSION.](#)

Abstract

Failing to account for transaction costs materially impacts inferences drawn when evaluating factor model performance, biasing tests in favor of models employing high cost factors such as the [Hou et al. \(2015\)](#) q -factor model and the [Barillas and Shanken \(2018\)](#) six-factor model. Ignoring transaction costs, these models have high maximum squared Sharpe ratios and small alphas across 120 anomalies. They do not, however, come close to spanning the *achievable* mean-variances efficient frontier. Accounting for transaction costs, the [Fama and French \(2015, 2018\)](#) five-factor model has a significantly higher squared Sharpe ratio than either of these alternative models. A variation of the [Fama and French \(2018\)](#) five-factor model employing cash profitability has an even higher squared Sharpe ratio, and better explains anomalies realizable performance.

1. Introduction

The finance literature documents hundreds of cross-sectional anomalies in stock returns (see, e.g., [Harvey et al., 2016](#)). One of the field’s central goals is to identify a parsimonious asset pricing model that can explain a wide range of anomaly performance. This has led researchers to propose numerous models, which has in turn generated multiple studies dedicated to choosing from among these models.¹

Ultimately the power each model has pricing assets simply reflects how close its factors come to spanning the efficient frontier. If a test asset generates abnormal returns relative to a model, that test asset improves the investment opportunity set. If some combination of the model’s factors are ex post mean-variance efficient, then no other asset can be used to improve performance, and the model prices everything. As a result, factor models are now typically evaluated based on how close their factors come to spanning the ex post efficient frontier, most commonly using the maximum squared Sharpe ratio criterion of [Barillas and Shanken \(2017\)](#).

Unfortunately these tests are misleading, at least as typically applied, regarding how close a model comes to spanning the efficient frontier. This fact is best illustrated with a simple example. A single factor based on one month industry-relative reversals, constructed using only stocks with below median volatility as in [Novy-Marx and Velikov \(2016\)](#), has a squared Sharpe ratio that is more than nine times the maximum squared Sharpe ratio of the [Fama and French \(1993\)](#) three factor model, and almost four times that of the [Fama and French \(2015\)](#) five factor model

¹ See., e.g., [Fama and French \(1993\)](#); [Hou, Xue, and Zhang \(2015\)](#); [Barillas and Shanken \(2018\)](#); [Fama and French \(1993, 2015\)](#); [Stambaugh and Yuan \(2017\)](#); [Fama and French \(2018\)](#); [Hou, Mo, Xue, and Zhang \(2019\)](#); [Barillas, Kan, Robotti, and Shanken \(2019\)](#); [Daniel, Hirshleifer, and Sun \(2019\)](#).

(4.81 versus 0.53 and 1.24, respectively). Despite this, no one seriously thinks that the single factor model based on low volatility industry-relative reversals is highly promising, despite its superior performance to all other candidate models under the criterion of [Barillas and Shanken \(2017\)](#).²

The basic problem is how the previous literature interprets the investment frontier. The theoretical underpinning of linear factor models, [Ross' 1976](#) Arbitrage Pricing Theory, is based on the idea that investment opportunities that generate abnormal returns attract arbitrage capital until they are eliminated. These opportunities only attract arbitrage capital in the real world, however, if they generate abnormal returns *in practice*. While low volatility industry-relative reversals have enormous alphas relative to standard factor models, they are also extremely expensive to trade. As a result, they are not very profitable in practice, and consequently do not attract significant arbitrage capital. That is, despite the strategy's ridiculous squared Sharpe ratio, it does not actually represent an attractive trading opportunity; its alpha does not indicate that it significantly expands the true achievable investment frontier.

This paper starts from the premise that arbitrage capital can only be expected to eliminate true abnormal trading opportunities, i.e., those that can be exploited profitably in practice. This is also the view taken by [Fama \(1991\)](#) when arguing that an “[economically] sensible version of the efficiency hypothesis says that prices reflect information to the point where the marginal benefits of acting on information (the profits to be made) do not exceed the marginal costs.” Starting from this premise

² This strategy's high gross Sharpe ratio does, however, make it attractive to machine learning algorithms designed to select factors. [Kozak, Nagel, and Santosh \(2019\)](#) estimate an SDF using 50 anomalies that puts more weight on this strategy than any other.

lowers the bar on what we should expect from an asset pricing model, because even the right model may allow for strategies with large “paper” alphas—there is no reason to expect even the correct model to price strategies that cannot be traded profitably. In this case the best models are simply those that parsimoniously span the achievable efficient frontier, fully describing the true investment opportunity set as simply as possible.

This paper reevaluates the performance of asset pricing models from this perspective, providing the first study on model selection that accounts for transaction costs. Accounting for transaction costs materially impacts our results, reversing several major conclusions relative to what the prior literature finds when ignoring transaction costs. Ignoring these costs biases prior studies in favor of models with factors constructed to maximize gross returns, even when this increases trading costs more than gross performance. For example, the mean-variance efficient portfolios of the factors in the [Hou et al. \(2015\)](#) four-factor model and the [Fama and French \(2018\)](#) five-factor model take similar positions in market, size, profitability, and investment factors. The size, investment, and profitability factors in the [Hou et al. \(2015\)](#) model are re-balanced more frequently, however, monthly instead of annually, and are constructed using a more complicated three-way sorting procedure that increases the over-weighting of small stocks. Both of these differences contribute to factor gross performance, but increase trading costs even more. As a result, while these differences improve gross performance, they diminish the performance an investor would actually realize. So while the [Hou et al. \(2015\)](#) model has a maximum squared Sharpe ratio that is almost 60% higher than the [Fama and French \(2018\)](#) model ignoring transaction costs, the maximum squared Sharpe ratio that the model’s factors could

have actually delivered was almost 40% lower.

Accounting for costs, the [Fama and French \(2018\)](#) models also outperform the most common alternative candidate models pricing a wide array of anomalies. Accounting for costs improves model performance in general, because many of the anomalies with the most impressive gross returns are also expensive to trade, and are thus less profitable, and less anomalous, on a net basis. The impact of diminished anomaly performance is partly offset by the lower net returns earned by the explanatory factors, but this is more acute for high turnover factors, resulting in improved relative performance for models employing low cost factors like the [Fama and French \(2018\)](#) models.

We also find, consistent with [Fama and French \(2018\)](#), that replacing the accruals-based profitability factor with one based on cash-based profitability significantly improves model performance. The net maximum squared Sharpe ratios for variations of the [Fama and French \(2018\)](#) five- and six-factor models that employ a cash-based profitability factor are more than a third higher than those on any of the other models we consider. These variations also span the other models, in the sense that an investor already trading these models' factors cannot significantly expand their opportunity set by additional trading another models' factors. These cash-based variations on the Fama and French model also generally perform better than other models pricing anomalies.

Overall, our results suggest caution when interpreting results from model selection studies. Linear factor models can only reasonably be expected to explain the portion of returns that arises as compensation for bearing risk, not implementation frictions. Once this insight is incorporated, the model selection landscape fundamen-

tally changes, because models that appear to perform strongly ignoring costs may actually have no power explaining the cross-section of returns available to investors.

2. Model comparison using maximum SR²

Factor models are often judged by how well they price test assets. Small abnormal returns relative to the model are the hallmark of a successful model, indicating that the factors come close to spanning the mean-variance efficient frontier. Conversely, if a test asset has a large abnormal return relative to the model, than an investor trading the factors can significantly expended their investment opportunity set by additionally trading the test asset.

Comparing factor models by how well they price test assets is problematic, however, for several reasons. First, the procedure generally lacks a formal statistical criteria for model selection. Given even a moderately challenging set of test assets, formal statistical tests generally reject all models. Models that are rejected less emphatically are consequently deemed “better” than models that are rejected more emphatically, even when tests do not actually directly compare models. The formal statistical tests used to test each individual model also perversely reward models that explain *less* test asset return variation. Greater residual variation reduces the precision with which the test assets’ factor model alphas are estimated, and thus their significance, which makes model reject less likely (or at least less emphatic). The procedure is also sensitive to which anomalies are used to test the models, often yielding contradictory answers when employing different sets of test assets. Using “anomalies” to test asset pricing models also always raises prima facie selection bias

concerns, particularly when comparing alternative candidate models to the canonical Fama and French (1993) three-factor model and its variations. Anomalies are usually defined by their high abnormal returns relative to the Fama and French (1993) model, biasing tests employing them as test assets against these models.

Partly in response to these issues, Barillas and Shanken (2017) introduce a summary statistic of model quality, the maximum SR^2 . This metric simply quantifies how close the span of a factor model is to the ex post mean variance efficient frontier of *all* assets. Higher SR^2 thus indicate lower test asset alphas relative to the model, in a precise sense that is strictly true for the appropriate combination of all test asset alphas.

2.1. The Barillas and Shanken (2017) maximum SR^2 test

Gibbons, Ross, and Shanken (1989) quantify the gains (ignoring transaction costs) from adding test assets to a set of factors using the increase in the maximum squared Sharpe ratio. They show that given a set of tradable factors with returns f , then adding test assets with excess returns Π yields an increase in the maximum squared Sharpe ratio of

$$SR^2(\Pi, f) - SR^2(f) = \alpha' \Sigma^{-1} \alpha,$$

where $SR^2(X)$ denotes the maximum possible Sharpe ratio attainable from X , α denotes the vector of intercepts from regressions of the test assets' excess returns on the factor returns, and Σ is the covariance matrix of residuals from these regressions.

While this metric of investment frontier expansion can be sensitive to the choice

of test assets (e.g., Lewellen, Nagel, and Shanken, 2010; Fama and French, 2018), Barillas and Shanken (2017) note that if Π is the entire universe of excess returns, then $SR^2(\Pi, f) = SR^2(\Pi)$ for any set of factor returns f , and the model with the lowest mispricing is thus precisely the one with the highest maximum squared Sharpe ratio. They consequently use the maximum squared Sharpe ratio as a model selection criterion, and this metric has seen wide adoption in the literature.³ We use the criterion here, but unlike earlier studies we account for transaction costs.

2.2. Candidate factor models

The candidate models come from Barillas and Shanken (2018) and Fama and French (2018). Barillas and Shanken (2018) compare the Fama and French (2015) five-factor model, sometimes augmented with a momentum factor, to the four-factor “ q -theory” model of Hou et al. (2015). They also construct their own preferred model, using the strongest combination of factors from the other models. We analyze these four models and, following Fama and French (2018), additionally consider versions of the Fama and French five- and six-factor factor models modified by replacing the standard profitability factor (RMW) with a variation based on cash profitability (RMW_C). Table 1 provides a simple summary of the factors employed in all six models, which for each factor includes the variable used for stock selection, the basic portfolio construction methodology, and the rebalancing frequency. A more detailed description of the factors is provided in Appendix A.1.

³ See, for example, Barillas and Shanken (2018), Fama and French (2018), Ferson, Siegel, and Wang (2019), and Barillas, Kan, Robotti, and Shanken (2019).

Table 1: Factor models employed in tests

For each of the asset-pricing models we consider in this paper, this table lists the non-market factors used by the model, denoted by a ‘x’ in the column below the model name, and three properties of the factors’ construction: the primary characteristics used to form the factor, ‘Primary sorting characteristic’, the frequency that each factor is updated, ‘Rebalance frequency’, and the sorting method used to form each factor, ‘Portfolio construction’. With the exception of SMB, factors with a portfolio construction of 2x3 are based on the six value-weighted portfolios resulting from the intersections of independent sorts of stocks into two groups based on size and three groups based on the primary sorting characteristic. With the exception of ME, factors with portfolio construction of 2x3x3 are based on the 18 value-weighted portfolios obtained from the intersections of independent sorts of stocks into two size groups, three groups based on a secondary characteristic besides size, and three groups based on the primary sorting characteristic. Breakpoints for size are based on the median market capitalization of NYSE stocks at the time of rebalancing and breakpoints for all other characteristics are based on the 30th and 70th percentiles of NYSE stocks. In all models, the factor returns are obtained as the equal-weighted average of the returns on the portfolios with high (or low) values of the primary sorting characteristic minus the equal-weighted average of the portfolios with low (or high) values. SMB returns are given by the simple average of the returns on all portfolios with low size minus the average of the returns on all portfolios with large size in three independent 2x3 sorts of stocks on size and each of the following characteristics: book-to-market ratio, growth in book assets, and operating profitability. ME returns are given by the simple average of the returns on all portfolios with low size minus those with large size in 2x3x3 sorts on size, growth in book assets, and return on equity. All models employ a market factor, MKT, which is the return on the CRSP value-weighted index in excess of the return on the 30-day Treasury-bill. FF5 and FF6 denote the [Fama and French \(2015, 2018\)](#) five- and six-factor models, respectively. HXZ4 denotes the [Hou et al. \(2015\)](#) four-factor q -model. BS6 denotes the [Barillas and Shanken \(2018\)](#) six-factor model. FF5_C and FF6_C denote versions of the FF5 and FF6, respectively, that use cash-based operating profitability instead of accruals operating profitability.

8

Factor	Sorting signal	Rebalancing	Construction	Models that employ the factor					
				FF5	FF6	HXZ4	BS6	FF5 _C	FF6 _C
SMB	Market capitalization	annual	2x3	x	x		x	x	x
HML	Book-to-market	annual	2x3	x	x			x	x
RMW	Accruals operating profitability	annual	2x3	x	x				
CMA	Growth in book assets	annual	2x3	x	x			x	x
MOM	Prior year’s stock performance, excluding most recent month	monthly	2x3		x		x		x
ME	Market capitalization	monthly	2x3x3			x			
IA	Growth in book assets	monthly	2x3x3			x	x		
ROE	Quarterly returns-on-equity	monthly	2x3x3			x	x		
HML(m)	Book-to-market	monthly	2x3				x		
RMW _C	Cash operating profitability	annual	2x3					x	x

Table 2: Factor summary statistics

This table presents average monthly returns, with t -statistics, for each of the asset pricing factors. It gives these both for the factors' gross returns and net of transaction costs. It also gives each factor's average monthly turnover, TO, and transaction costs, TC. MKT, SMB, HML, RMW, CMA denote the [Fama and French \(2015\)](#) market, size, value, profitability, and investment factors, respectively. MOM denotes the [Fama and French \(2018\)](#) momentum factor. RMW_C denotes the [Fama and French \(2018\)](#) cash profitability factor, which is constructed similarly to RMW but based on cash based, not accruals based, operating profitability. ME, ROE, and IA denote the [Hou et al. \(2015\)](#) size, profitability, and investment factors, respectively. HML(m) denotes the monthly updated value factor of [Asness and Frazzini \(2013\)](#). The sample period covers January 1972 through December 2017.

	Average returns				TO (%)	TC (%)
	Gross	t -statistic	Net	t -statistic		
MKT	0.56	2.95	0.56	2.95		
SMB	0.20	1.52	0.17	1.31	2.85	0.03
HML	0.36	2.89	0.31	2.45	5.10	0.05
RMW	0.28	2.79	0.22	2.23	5.27	0.05
CMA	0.31	3.75	0.22	2.61	9.76	0.09
MOM	0.66	3.56	0.19	1.03	51.40	0.47
ME	0.27	2.07	0.12	0.89	18.62	0.15
ROE	0.55	5.00	0.22	2.01	36.36	0.33
IA	0.38	4.82	0.16	2.03	24.59	0.22
HML(m)	0.34	2.21	0.14	0.90	19.37	0.20
RMW_C	0.36	4.52	0.29	3.58	7.36	0.07

Table 2 provides summary statistics for the factors. It gives the average monthly returns, with t -statistics, both ignoring transaction costs (“gross”) and net-of transaction costs (“net”), along with average monthly turnover (TO) and average monthly trading costs (TC). All the factors except for SMB have statistically significant average gross returns, ranging from 0.28% to 0.66% per month (RMW and MOM, re-

spectively).⁴ The turnover and transactions tend to be relatively high for factors that re-balance monthly, which also tend to be those with higher average gross returns. The turnover on the factors rebalanced monthly, MOM, ROE, IA, and HML(m), ranges from 22.3% to 52.7% per month, an order of magnitude higher than the 3.7% to 10.7% average monthly turnover on the annually re-balanced factors, SMB, HML, RMW, and CMA. As a result, the net-of-costs average returns of the former are generally insignificant after costs. This extends prior evidence from [Lesmond et al. \(2004\)](#) that momentum, while seemingly highly profitable before costs, hardly profitable after costs.

2.3. Model maximum squared Sharpe ratios

Figure 1 graphically depicts a key result of the paper. The Hou-Xue-Zhang four-factor model and the Barrilas-Shanken six-factor model have both been constructed specifically to get closer to the ex post mean-variance frontier. They have been constructed, however, without any concern for transaction costs. As a result, both these models have higher gross squared Sharpe ratios than the Fama and French models, despite actually moving an investor farther from the achievable investment opportunity set.

Moving across the dark (blue) bars, Figure 1 shows an upward sloping pattern. The FF5 models gross SR^2 is 1.24. Adding a momentum factor (FF6) increases this to 1.62. The HXZ model's gross SR^2 is 2.01, and the BS6 model's is 2.75. These squared Sharpe ratios are fictitious, however, because they do not actually represent

⁴Transaction costs are calculated as in [Novy-Marx and Velikov \(2016\)](#), using the stock-level effective spread measure of [Hasbrouck \(2009\)](#). This measure captures the substantial cross-sectional heterogeneity in stocks prices, and is broadly available over our whole sample. A more detailed description of the methodology is provided in Appendix [A.2](#).

Figure 1: Maximum squared Sharpe ratios of factor models. This figure presents maximum squared Sharpe ratios from the factors in the models listed on the x-axis. The blue columns, ‘Gross $SR^2(f)$ ’, use factor returns that ignore transaction costs. The red columns, ‘Net $SR^2(f)$ ’, use factor returns that account for transaction costs. The sample period is January 1972 to December 2017.

what an investor could have achieved. The achievable investment opportunity set is what is relevant for directing arbitrage capital.

The pattern for the net squared Sharpe ratios, which directly reflect the best risk-reward trade-off that an investor could have achieved in practice, looks very different. While the HXZ and BS6 models have higher gross squared Sharpe ratios than the Fama and French models, these models’ factors are more expensive to trade, and these models’ spans are consequently actually farther from the achievable efficient frontier. The Fama and French five- and six-factor models’ net squared Sharpe ratios of 0.81 and 0.89 exceed the HXZ and BS6 models’ 0.60 and 0.74.

The performance of the Fama and French model variations that include the cash profitability factor are more impressive still. While the gross squared Sharpe ratio

of the Fama and French five-factor model that includes cash profitability is 1.94, slightly lower than that of the HXZ model, its net squared Sharpe ratio is 1.29, more than twice that of the HXZ model. Adding the momentum factor only marginally improves the net squared Sharpe ratio of the Fama and French model that uses the factor based on cash profitability, to 1.33. This model dominates the others, in the sense that adding all the other models factors does not expand the investment opportunity set. Untabulated result show that the net squared Sharpe ratio of the 11-factor model that includes all the factors form all four models is the same 1.33 as that on the cash profitability version of the Fama and French six-factor model alone.

Table 3 reports portfolio weights in ex post mean-variance efficient portfolios constructed using factors from the six candidate asset pricing models, i.e., the holdings of the portfolios that yield the squared Sharpe ratios shown in Figure 1. Panel A gives the weights an investor would have liked to have held in each factor, provided they could have traded completely costlessly. It shows that the HXZ model improves on the gross squared Sharpe ratio of the FF5 model essentially by swapping out the Fama and French size, profitability, and investment factors for their own versions of these factors, which rebalance more frequently and are constructed using a more complicated three-way sorting procedure. Similarly, the BS6 model improves on the gross squared Sharpe ratio of the FF6 model essentially by swapping out the Fama and French profitability factor for HXZ profitability factor, and shifting the weight on the Fama and French investment factor to a value factor that rebalances monthly, largely in response to stock price performance, which results in a large negative correlation with momentum. The Fama and French model variations that use cash profitability improve on the standard versions essentially by moving all the of weight

on RMW, and a third of the weight on CMA, to RMW_C , which has a much higher Sharpe ratio than the profitability factor based on accrual-based profitability.

Table 3: Ex post mean-variance efficient portfolios

For each of the asset-pricing models specified by the row headings, this table presents the weights of each factor in the portfolio consisting of the model's factors that maximizes the ex-post squared Sharpe ratio, $SR^2(f)$. Panel A uses factor returns that ignore transaction costs. Panel B uses factor returns that account for transaction costs. The sample period spans January 1972 through December 2017.

Panel A: Results ignoring transaction costs												
Optimal factor weight (% of holdings in the ex post MVE portfolio)												$SR^2(f)$
MKT	SMB	HML	RMW	CMA	MOM	ME	ROE	IA	HML(m)	RMW _C		
FF5	18	10	-1	29	42							1.24
FF6	18	8	7	23	32	12						1.62
HXZ4	15						13	30	42			2.01
BS6	13	10				14		29	9	25		2.75
FF5 _C	16	13	-1		26						44	1.94
FF6 _C	16	11	4		22	8					39	2.22
Panel B: Results accounting for transaction costs												
Optimal factor weight (% of holdings in the ex post MVE portfolio)												$SR^2(f)$
MKT	SMB	HML	RMW	CMA	MOM	ME	ROE	IA	HML(m)	RMW _C		
FF5	21	10	4	30	35							0.83
FF6	20	9	8	26	29	7						0.90
HXZ4	22						9	27	42			0.60
BS6	17	12				8		28	17	18		0.74
FF5 _C	18	13	2		20						46	1.29
FF6 _C	18	13	4		18	4					43	1.33

Panel B reports results accounting for transaction costs. While the portfolio holdings are similar, the net factor returns are lower by the cost of trading, and the squared Sharpe ratios that could have actually been realized are consequently reduced by 33-73%. This reduction is greater for models employing high turnover factors. As a result, the FF5 and FF6 models have higher net squared Sharpe ratios than the HXZ and BS6 models (0.83 and 0.90 versus 0.60 and 0.74), despite having gross squared Sharpe ratios that are significantly lower. The net squared Sharpe ratios of the Fama and French five factor model variation that employs cash profitability is much higher, 1.29. For this model, including momentum only yields marginal performance improvements, increasing the net squared Sharpe ratio to 1.33.⁵

2.4. Direct measures of frontier expansion

Barillas and Shanken (2017) show that one asset pricing model is superior to another, under the maximum squared Sharpe ratio criterion, if the first model's factors price the second model's factors but the converse is false. Adding the superior model's factors to the inferior model expands the investment opportunity set, and thus the SR^2 , but adding the inferior model's factors to the superior model, relative to which they have no alpha, does not improve an investors opportunities relative to just the factors in the superior model alone.

In the presence of transaction costs the common notion of alpha can no longer be interpreted as a measure of abnormal investment opportunities, because it does not represent anything an investor could actually exploit, which makes quantify-

⁵ HML also adds little to the Fama and French model variation based on cash profitability, because CMA and HML are positively correlated and thus play a similar role. The four factor model employing MKT, SMB, CMA, and RMW_C has a squared Sharpe ratio of 1.28, statistically indistinguishable from the 1.29 on the five factor model that additionally includes HML.

ing frontier expansion slightly more complicated. We can measure the extent to which adding one model’s factors to another model expands the frontier, however, using a multi-factor version of the generalized alpha measure of [Novy-Marx and Velikov \(2016\)](#). This directly measures the improvement in the mean-variance efficient returns an investor could actually realize, net of transaction costs, by adding the additional factors to the set of available assets. Specifically, we use the alpha from a regression of the returns of the ex post mean-variance efficient portfolio of the union of the two models’ factors onto the returns of the ex post mean-variance efficient portfolio of the factors from just the base model alone,

$$MVE_{M1 \cup M0,t} = \alpha + \beta MVE_{M0,t} + \epsilon_t, \quad (1)$$

where MVE_X denotes the excess return of the ex-post tangency portfolio consisting of the factors X . The α ’s magnitude cannot be directly interpreted without re-scaling, but its statistical significance is directly proportional to the extent to which the factors in $M1$ improve the achievable investment frontier beyond that available from trading just the factors in $M0$.⁶

Panel A of Table 4 presents results of these spanning regressions, both before- and net-of-costs, for each pair of models. Panel B also reports, as a measure of the economic significance, the percent increase in the maximum squared Sharpe ratio that results from adding the additional factors to the base model for each pair, which reflects the utility gain that could be realized by a mean-variance investor.

⁶ [Novy-Marx and Velikov \(2016\)](#) show that if $M1$ is a single test asset and there are no transaction costs, then the alpha from this regression, scaled by the weight of the test asset in the mean-variance efficient portfolio of the factor model and the test asset, agrees exactly with the common notion of alpha.

The left panel, which presents results ignoring transaction costs, shows that on a pre-cost basis, most of the models expand the investment frontier when added to others, though the HXZ model spans the standard Fama and French five-and six factor models, and the BS6 model spans the HXZ model. The right panel, which shows results accounting for transaction costs and is thus more relevant, shows very different results. Here the standard Fama and French models significantly expand the achievable investment opportunity space relative to the HXZ or BS6 models alone, while these models' factors do not expand the achievable investment opportunity space relative to the Fama and French six-factor model, and only marginally improve that of the Fama and French five-factor model. Perhaps most strikingly, the bottom two rows show that none of the models significantly expand the achievable investment opportunity space for an investor already trading the variations of the Fama and French five-factor model that employs cash profitability. That is, this model spans the others, and even adding a momentum factor does not significantly improve the model's performance.

Table 4: Spanning regressions

Panel A reports intercepts from regressions of the form $MVE_{M0 \cup M1,t} = \alpha + \beta \cdot MVE_{M0,t} + \epsilon_t$, where MVE_{M0} denotes the excess returns to the ex-post mean-variance-efficient portfolio of the factors in models $M0$, and $MVE_{M0 \cup M1}$ denotes the same for the model made by augmenting $M0$ with the factors from model $M1$. The t -statistics, given in square brackets, are robust to heteroskedasticity. Column headings specify the $M1$, while rows specify the $M0$. Panel B quantifies the economic significance of these intercepts, using the fractional increase in the maximum squared Sharpe ratio resulting from augmenting the column model with the factors from the row model, $\% \Delta SR^2(M0, M1) = SR^2(M0, M1) / SR^2(M0) - 1$. Results are given both ignoring transaction costs (Gross), and accounting for these costs (Net). The sample spans January 1972 through December 2017.

3. Model performance in bootstrap simulations

The maximum squared Sharpe ratio, $SR^2(f)$, is useful for direct model comparison, but is only a simple summary statistic. While informative about which models' span was closer to the ex post mean variance efficient frontier of all assets, it provides little information regarding how likely it is that a “good” model will beat a “bad” model going forward. We can answer questions of that sort, however, using bootstraps. These simulations allow us to get a sense of the full distribution of potential maximum squared Sharpe ratios for each model, and to make estimates of the probability of any one model beating any other model, or of beating all the other models, over some sample going forward. They can also be used to evaluate the significance of the difference in maximum squared Sharpe ratios of two non-nested models.

Bootstraps have the further advantage that they can be used to generate both in-sample (IS) and out-of-sample (OS) results. The IS results are directly comparable to the true in-sample results reported in Figure 1 and Table 3 but, like the true in-sample results, are biased upward (see, for example, DeMiguel et al., 2009). For these, in each bootstrap run we use the same simulated return series both to select the optimal weights on any model's factors, and to calculate this portfolio's returns. This biases the $SR^2(f)$, because the MVE weights are overfit, yielding the highest possible in-sample Sharpe ratio, despite being only noisy estimates of the true optimal weights. The IS maximum squared Sharpe ratios are consequently higher than what an investor can expect going forward.

The OS results, while not directly comparable to the true in-sample results, more accurately reflect what investors can hope to achieve in practice. For these, in each bootstrap run we estimate optimal portfolio weights as in the IS runs, but

calculate portfolio performance using an alternative set of simulated factor returns. The performance of these portfolios, which are largely free from the look-ahead bias that plagues the IS portfolios, is much less impressive, but more representative of potential perspective performance.⁷

The actual bootstrap procedure follows [Fama and French \(2018\)](#). To be certain that the OS results do not use any in-sample information, we need to ensure that the returns from months used to calculate portfolio performance are distinct from the those used to estimate the optimal portfolio weights. At the start of each bootstrap run we consequently partition the whole sample into IS month and OS months. To do this, one of each consecutive pair of months is randomly assigned to the IS sample, with its partner month assigned to the OS sample. The IS factor returns are created by sampling, with replacement, from the IS sample months, with the OS returns constructed using the corresponding partner months. For each run we compute maximum squared Sharpe ratios, $SR^2(f)$, both IS and OS, for each model, and compare these to each other. Reported results are based off 100,000 runs of the longest practicable sample size, 23 years (276 months), which is half the length of the full data sample, January 1972 through December 2017.

Table 5 presents the formal statistical comparison of the differences between the net-of-costs Sharpe ratios of each model. Panel A presents in-sample (IS) results. The IS $SR^2(f)$ are biased upwards, so their level should be interpreted with caution.⁸ With that caveat, the average IS net $SR^2(f)$ is higher for the FF5 and FF6 models

⁷ The OS results are themselves not completely free from all potential biases, as the factors under consideration were themselves selected using the full sample data.

⁸ These results are even more biased than the true in-sample results given in Table 3, because the sample is shorter, yielding more acute overfitting of the optimal weights. Appendix Table B.1 shows IS bootstrap results for a sample length of 552 months, the same length as our true in-sample results, and reports similar maximum squared Sharpe ratios.

than for the HXZ4 and BS6 models. Moreover, the FF6 model outperforms the HXZ4 in over 95% of the samples, and the BS6 model in over 77% of the samples.

Panel B presents out-of-sample (OS) results, which are bias-free. The average OS net-of-costs $SR^2(f)$ of the FF5 and FF6 models are closer, but still higher compared to those of the HXZ4 and BS6 models. The net-of-costs OS $SR^2(f)$ of the FF5 and FF6 are greater than those of the HXZ4 and BS6, respectively, in more than 65% of the bootstrap samples. Overall, the evidence in Figure 1 and Tables 3 and 5 shows that the FF5 and FF6 models tend to dominate the HXZ4 and BS6 after costs because of the latter models' high turnover and transaction costs. This finding essentially reverses the comparisons of Hou et al. (2019) and Barillas and Shanken (2018). The Fama and French model variations that employ cash-based profitability have far stronger performance still, with average maximum squared Sharpe ratios that are more than 50% higher than their conventional counterparts, Sharpe ratios close to one. In fact, in 92% of the runs the FF5C or FF6C model is the best performing model. The performance of these two models is surprisingly similar. The five-factor version actually has a slightly higher average squared Sharpe ration than the six-factor version, which also includes momentum, though the six-factor version outperforms the five-factor version slightly more often it underperforms it. In 23.8% of runs momentum is excluded from the MVE portfolio of the FF6C factors. In the remaining runs, 41.8% of the time it improves OS performance, but almost as often, 34.4% of the time it diminishes OS performance. That is, almost half the time an investor in these factors takes a position in momentum they end up regretting it ex post.

Table 5: Bootstrapped net-of-costs maximum squared Sharpe ratios

For each model we consider, the first column presents average net-of-costs maximum squared Sharpe ratios, $SR^2(f)$, from 100,000 in-sample (IS) or out-of-sample (OS) simulation runs. IS and OS simulations split the 552 sample months of our sample period, January 1972 through December 2017, into 276 adjacent pairs: months (1, 2), (3, 4), ... (551, 552). A simulation run draws a random sample with replacement of 276 pairs. The IS simulation run chooses a month randomly from each pair in the run. We calculate IS $SR^2(f)$ on that sample of months and then apply the corresponding portfolio weights in the unused months of the simulation pairs to produce the corresponding OS estimate of the Sharpe ratio for the IS tangency portfolio. The six columns labeled by model names, ‘FF5’ to ‘FF6C’, present the percentage of bootstrap simulations in which the squared Sharpe ratio of the model defined by the row heading is greater than or equal to that of the model defined by the column heading. The last column, ‘Best’, presents the percentage of bootstrap simulation runs in which the model specified by the row heading has the highest squared Sharpe ratio among all models in the run. Panel A presents IS results and Panel B presents OS results. The sample period is January 1972 through December 2017.

Panel A: In-sample bootstrap results								
		Probability (%) that the row model performs at least as well as the column model

FF6 _C	1.03	93.8	97.8	95.3	96.2	65.6		60.1

4. Model performance explaining anomalies

This section takes an alternative, throwback approach to factor model comparison. Instead of studying ability of the factor models to price each other’s factors, this approach compares the models’ ability to price a given set of anomaly portfolios. Lacking a formal criteria for choosing an ideal set of test assets, we simply employ the most comprehensive set of net-of-cost anomaly returns that we know of, the 120 anomaly long/short portfolios from [Chen and Velikov \(2019\)](#).⁹ These are constructed from the usual data sources; more than half of the predictors are constructed using Compustat data, while almost a third use only market pricing data available from CRSP. Most of the remainder use analyst forecasts, though several focus on institutional ownership data, trading volume, or specialized data. For further details, see [Appendix C](#).

For this approach we also rely on the squared Sharpe ratio as a comparison criterion. For each model M taken from the six candidate models, and for each A taken from the 120 anomalies, we compute the maximum squared Sharpe ratios attainable from the model’s factors alone, $SR^2(M)$, and from the model’s factors augmented with the anomaly, $SR^2(M, A)$. We then compute the extent to which adding the anomaly expands the model’s ex-post mean-variance frontier, $\% \Delta SR(M, A) = SR^2(M, A)/SR^2(M) - 1$. We do this using both gross- and net-of-costs returns. In each case we then rank the anomalies for each model based on this measure.

⁹These anomalies are distilled from a set of 156 cross-sectional return predictors employed by [Chen and Zimmerman \(2018\)](#), taken from 115 publications in accounting, economics, and finance journals. [Chen and Velikov \(2019\)](#) remove 34 predictors that do not reliably produce return spreads in decile sorts, and 2 predictors they deem are due to risk, to arrive at the final set of 120 anomalies.

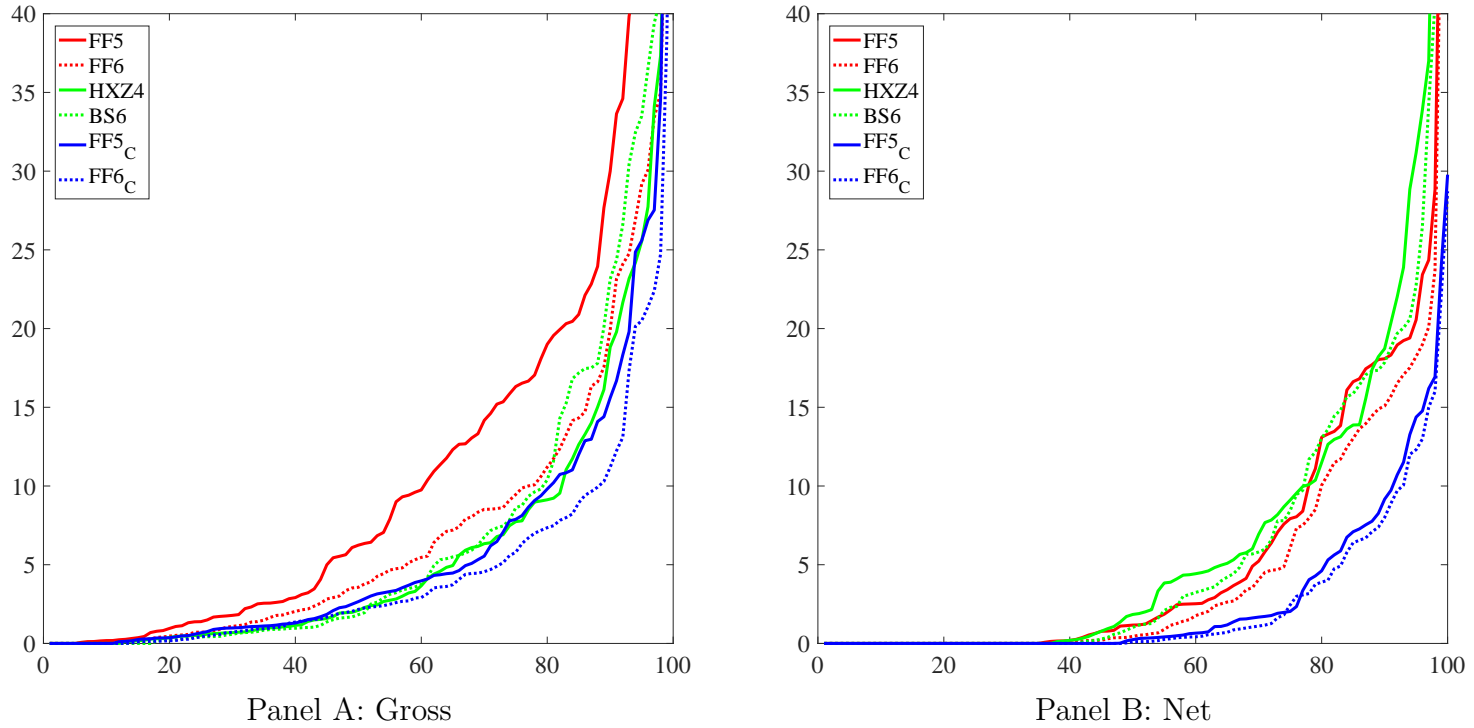

Figure 2: Frontier expansion (squared Sharpe ratio improvement) from adding anomalies to asset-pricing models. For each asset-pricing model we consider, M , and each of the 120 anomalies, A , described in Section 4, we compute the maximum ex-post squared Sharpe ratio attainable from the model's factors, $SR^2(M)$, along with the maximum squared Sharpe ratio attainable from the model's factors and the anomaly, $SR^2(M, A)$. We then compute the squared Sharpe ratio improvement, $\% \Delta SR(M, A) = SR^2(M, A) / SR^2(M) - 1$. This figure depicts plots of the percentiles from the distribution of the 120 $\% \Delta SR(M, A)$ for each model specified by the plot legend. Panel A (B) ignores (accounts for) transaction costs. For ease of visualization, the y-axes are truncated at 40%.

Figure 2 shows plots of the extent to which the anomalies improve each models' squared Sharpe ratio, with the smallest improvements on the left and the greatest on the right. If one model's line is below another, then across the distribution the anomalies expand the frontier of the first model less than they do the second, suggesting that it better prices anomalies.

Panel A, which shows results ignoring transaction costs, is consistent with the work of Hou et al. (2015). It shows that the anomalies generally expand the frontier for the Fama and French five-factor model more than they for the HXZ or BS6 models, which perform similarly to the five-factor model augmented with momentum.

The right panel, which shows results net of transaction costs, looks very different. First, in each case nearly half the anomalies contribute almost nothing to frontier expansion. That is, only half of anomalies seem at all anomalous after accounting for costs. Here the lines for the Fama and French five- and six-factor models tend to be below those for the HXZ and BS6 models, suggesting that these models, presented as improvements on the standard models, actually perform worse at explaining achievable investment performance. Perhaps most strikingly, the lines corresponding to the Fama and French model variations that employ cash profitability dominate the other models, admitting much smaller frontier expansions across the whole distribution.

Table 6 provides summary statistics for the data depicted in Figure 2. It reports the mean, standard deviation, and select percentiles from the distribution of $\% \Delta SR(M, A)$ across the 120 anomalies for each model, and tells a similar story. While ignoring costs the HXZ4 and BS6 perform somewhat better than the standard Fama and French models pricing anomalies, this advantage disappears after accounting for the cost of trading, and the Fama and French variations that employ

Table 6: Anomaly frontier expansion summary statistics.

For each model, M , specified by the row heading, and each of the 120 anomalies, A , described in Section 4, we compute the ex-post maximum squared Sharpe ratio attainable from the model’s factors, $SR^2(M)$, and that attainable from the model’s factors and the anomaly, $SR^2(M, A)$. We then compute the squared Sharpe ratio improvement, $\% \Delta SR(M, A) = SR^2(M, A)/SR^2(M) - 1$. For each model we consider, this table reports the mean, standard deviation, ‘Std’, and select percentiles from the distribution of $\% \Delta SR(M, A)$ across the 120 anomalies. Panels A and B, respectively, present results using before-costs and net-of-costs returns.

Panel A: Gross									
Model	Mean	Std	Percentiles						
			25	50	75	90	95	99	100
FF5	11.9	16.8	1.4	6.2	16.3	30.0	43.1	83.3	123.6

FF6 _C	2.3	4.6	0.0	0.1	2.4	8.0	12.3	22.1	28.7

cash profitability explain far more of anomaly performance an investor could actually capture than any of the other models.

5. Models using cost-mitigated factors

The HXZ and BS6 models do not outperform the standard model on a net basis. They were built to perform well on a gross basis, without regards for transaction costs, and are consequently expensive to trade, impairing their performance in practice. They should perform better, however, if designed in a manner which reduces the cost of trading their factors. We consequently now consider the performance of models that employ factors constructed with “banding,” the single most effective cost mitigation technique investigated by [Novy-Marx and Velikov \(2016\)](#).

The banded strategies employ a buy/hold spread at each break point. This introduces trading hysteresis, dramatically reducing turnover. Specifically, at each break point we introduce a 20% spread. For a tertile break point, instead of trading at each rebalance point to hold stocks with sorting characteristic more extreme than 30% of NYSE firms, we buy stocks that have entered the top 20% and continue to hold any stocks that we already held provided they remain in the top 40%. For the median breakpoint, we buy stocks entering the top 40% and continue to hold current positions until they leave the top 60%.

Table 7 gives summary statistics for factors constructed using these soft boundaries, including average monthly returns, turnover, and transaction costs. These factors have similar average gross performance, but roughly a third less turnover, and commensurately lower transaction costs, than their conventionally constructed counterparts.

Table 7: Cost-mitigated factor summary statistics: mean monthly return, turnover, and transaction costs

This table presents average monthly returns and t -statistics, both gross and net of transaction costs, along with average monthly turnover, TO, and transaction costs, TC, of versions of the asset-pricing factors defined in Table 2 that employ the 20% banding cost-mitigation strategy described in Section 5. The sample period is January 1972–December 2017 ($n = 552$).

	Average monthly excess returns				TO (%)	TC (%)
	Gross	t -statistic	Net	t -statistic		
MKT	0.56	2.95	0.56	2.95		
SMB	0.16	1.22	0.14	1.07	1.88	0.02
HML	0.35	2.78	0.32	2.50	3.09	0.03
RMW	0.22	2.37	0.18	1.94	3.46	0.04

MOM	0.74	3.91	0.46	2.46	28.1	0.28
ME	0.24	1.91	0.11	0.89	14.5	0.13
ROE	0.58	4.88	0.33	2.80	25.3	0.24
IA	0.47	5.50	0.29	3.36	19.0	0.18
HML(m)	0.30	2.06	0.23	1.54	6.56	0.08
RMW _C	0.32	3.62	0.26	2.98	5.38	0.05

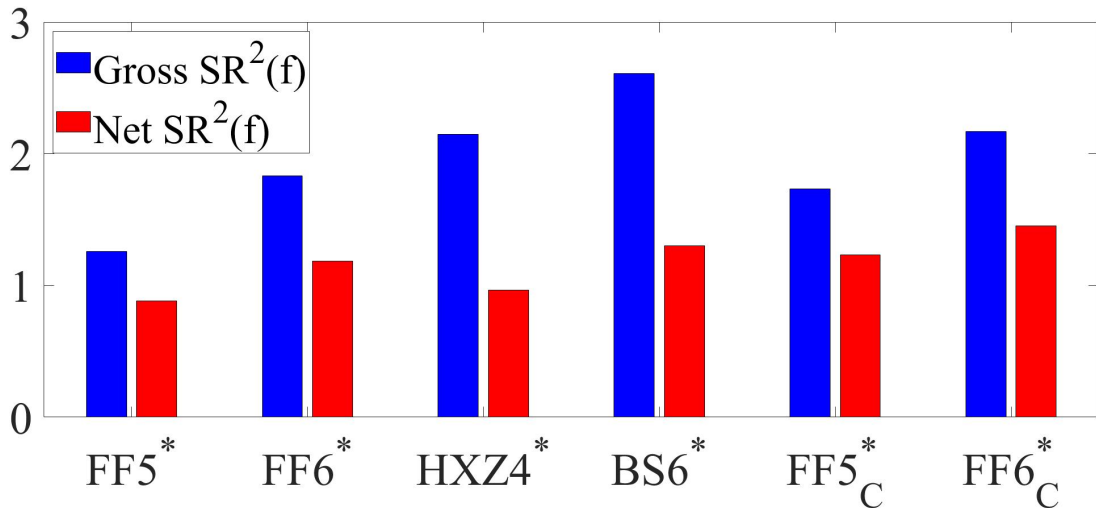

Figure 3: Maximum squared Sharpe ratios of cost-mitigated factor models. This figure presents maximum squared Sharpe ratios from the factors in the models listed on the x-axis. The blue columns, ‘Gross $SR^2(f)$ ’, use factor returns that ignore transaction costs. The red columns, ‘Net $SR^2(f)$ ’, use factor returns that account for transaction costs. The factors are all versions that use the 20% banding cost-mitigation strategy described in Section 5. The sample period is January 1972 to December 2017.

Figure 3 and Table 8 replicate Figure 1 and Table 3 for the models using the cost mitigated factors. They show the maximum squared Sharpe ratios, both accounting for and ignoring transaction costs, and give the weights in the ex-post mve portfolios for each models’ factors.¹⁰ Overall the results are very similar to those presented earlier, with a few important differences. All of the models perform better on a net basis, because they are more transactionally efficient. The improvements are more pronounced for the models that employ higher turnover factors, because transactional efficiency yields greater benefits when costs are higher. As a result, there is less distinction between model performance, though the Fama and French six-factor

¹⁰ Model spanning tests analogous to those provided in Table 4, which show similar results, can be found in Appendix Table D.1.

model variation employing the cash profitability factor is still the best performing model. It outperforms its five-factor counterpart because the momentum factor, which has the highest turnover and highest trading costs of all the factors, benefits the most from efficient construction, and consequently adds more when included in a model.

Table 9 shows bootstrap results analogous to those provided in Table 5, both in-sample (IS) and out of sample (OS), for the models that employ the cost mitigated factors. It shows that while the Fama and French six-factor model is still the best performing model more than 60% of the time in-sample, and almost half the time out of sample, the BS6 model is a stronger contender, performing best in-sample more than a third of the time and out of sample more than a quarter of the time. This partly reflects the greater contribution of momentum to model performance when factors are designed to be transactionally efficient. This is also reflected in the fact that investors that chose to trade momentum because of its in-sample performance only regret trading it ex post a little over a quarter of the time, significantly less frequently than the nearly half the time they did when trading the momentum factor designed without regards for reducing transaction costs.

Table 8: Ex post mean-variance efficient portfolios of cost-mitigated factor models

For each of the factor models specified by the row headings, this table presents the weights of each factor in the portfolio consisting of the model's factors that maximizes the ex-post squared Sharpe ratio, $SR^2(f)$. The factors are all versions that use the 20% banding cost-mitigation strategies described in Section 5. Panel A uses factor returns that ignore transaction costs. Panel B uses factor returns that account for transaction costs. The sample period is January 1972 to December 2017.

Table 9: Bootstrapped net-of-costs maximum squared Sharpe ratios using cost-mitigated factors

For each model we consider, the first column presents average net-of-costs maximum squared Sharpe ratios, $SR^2(f)$, from 100,000 in-sample (IS) or out-of-sample (OS) simulation runs. IS and OS simulations split the 552 months of our sample period, January 1972 to December 2017, into 276 adjacent pairs: months (1, 2), (3, 4), ... (551, 552). A simulation run draws a random sample with replacement of 276 pairs. The IS simulation run chooses a month randomly from each pair in the run. We calculate IS $SR^2(f)$ on that sample of months and then apply the corresponding portfolio weights in the unused months of the simulation pairs to produce the corresponding OS estimate of the Sharpe ratio for the IS tangency portfolio. The six columns labeled with model names, ‘FF5’ to ‘FF6C’, present the percentage of bootstrap simulations in which the squared Sharpe ratio of the model defined by the row heading is greater than or equal to that of the model defined by the column heading. The last column, ‘Max’, presents the percentage of bootstrap simulation runs in which the model specified by the row heading has the highest squared Sharpe ratio of all models in the run. All models use versions of the factors that employ the 20% banding strategy described in Section 5. Panel A presents IS results and Panel B presents OS results. The sample period is January 1972 to December 2017.

6. Conclusions

In a world with implementation costs, even the “right” risk-based asset-pricing model should not completely explain the cross-section of before-cost expected returns, but only the portion that arises as compensation for risk. We investigate which asset pricing models explain the cross-section of returns after transaction costs are taken into account. The results in this paper show that correcting for costs fundamentally alters the outcome of model selection exercises. Prior model-selection studies tend to pick factors that update at the monthly frequency, which gives them an unrealizable and illusory advantage over models with factors that update only annually. However, after costs are considered, the models with less frequent re-balancing tend to outperform.

A. Data and methods

This section describes our data sources and methods. Based on data availability, our sample is January 1972 through December 2017.

We compare the net-of-costs performance of four empirical factor models: the [Fama and French \(2015\)](#) five-factor model, the [Fama and French \(2018\)](#) six-factor model, the [Hou, Xue, and Zhang \(2015\)](#) four-factor model, and the [Barillas and Shanken \(2018\)](#) six-factor model. To calculate the transaction costs associated with trading each factor, we follow [Novy-Marx and Velikov \(2016\)](#) and use the effective bid-ask spread estimator of [Hasbrouck \(2009\)](#). The anomalies we use for the LHS approach are from [Chen and Velikov \(2019\)](#). Finally, we employ the [Novy-Marx and Velikov \(2016\)](#) generalized alpha to evaluate the pricing performance of the models we study.

A.1. Factor models

We compare the performance before and after applying our trading cost measure to six empirical asset-pricing models that are used in recent model-selection studies.

- FF5: The five-factor model of [Fama and French \(2015\)](#) has factors MKT, SMB, HML, RMW, and CMA. MKT denotes the return on the CRSP value-weighted stock market index in excess of the risk-free rate. SMB is a size factor that is long stocks with small market capitalization and short stocks with large market capitalization, HML is a value factor that is long stocks with high book-to-market ratios and short stocks with low book-to-market ratios. RMW is a profitability factor that is long stocks with high (robust) operating profitability and short stocks with low (weak) operating profitability. CMA is an investment

factor that is long stocks with low (conservative) investment and short stocks with high (aggressive) investment.

- FF6: The six-factor model of [Fama and French \(2018\)](#) constructed as FF5 augmented by MOM, the momentum factor of [Carhart \(1997\)](#). The momentum factor is re-balanced monthly and is long (short) stocks with the highest (lowest) returns over the prior 12 months excluding the prior month.
- HXZ4: The four-factor q -model of [Hou et al. \(2015\)](#) has factors MKT, ME, IA, and ROE. ME is a size factor that is long stocks with low market capitalization and short stocks with high market capitalization, IA is an investment factor that is long stocks with low investment and short stocks with high investment, and ROE is a factor that is long stocks with high profitability (from the most recent quarterly earnings) and short stocks with low profitability.
- BS6: The six-factor model of [Barillas and Shanken \(2018\)](#). [Barillas and Shanken \(2018\)](#) use a Bayesian technique to compare the factors of FF6, HXZ4, and HML(m), which is the monthly-updated value factor of [Asness and Frazzini \(2013\)](#). They conclude that the dominant model includes six factors: MKT, SMB, IA, ROE, MOM, and HML(m).
- FF5_C: The five-factor model of [Fama and French \(2015\)](#) where the RMW factor is replaced by a profitability factor RMW_C that is constructed similarly, but replaces operating profitability with cash operating profitability following [Ball et al. \(2016\)](#).
- FF6_C: The six-factor model of [Fama and French \(2015\)](#) where the RMW factor is replaced by a profitability factor RMW_C that is constructed similarly, but

replaces operating profitability with cash operating profitability following [Ball et al. \(2016\)](#).

The details of the construction of the factors used in the four factor models above plays a crucial role in our analysis. All stock characteristic-based factors in FF5 (SMB, HML, RMW, and CMA) are constructed by rebalancing the underlying portfolios once a year, at the end of each June. By contrast, the MOM factor, as well as the characteristic-based factors in HXZ (ME, IA, ROE) and the value factor in BS6 (HML(m)), are all rebalanced monthly.

We obtain before-costs returns on each Fama-French factor except RMW_C from the website of Kenneth French along with data on the small-cap portfolios necessary to make HML_S , MOM_S , RMW_S , and CMA_S from the 6 portfolios formed on size and each of the other relevant characteristics. We replicate the before-cost returns on the RMW_C factor using CRSP and COMPUSTAT data following [Fama and French \(2018\)](#). We obtain before-cost returns on the HXZ4 factors directly from Chen Xue, and on the HML(m) factor from the website of AQR. We replicate all factors with correlations between the original and replicated versions ranging from 0.97 to 1.00.

Below we argue that the most important difference in performance stems from the construction of the respective profitability factors in FF5 and HXZ4 - RMW and ROE. While RMW rebalances portfolios annually by sorting stocks on a measure of operating profitability derived from the COMPUSTAT annual files, the ROE factors rebalances portfolios monthly by sorting stocks on a measure of return-on-book-equity derived from the COMPUSTAT quarterly files. The monthly updating using quarterly data requires much higher turnover, thereby inducing much higher trading

costs.

Another major difference between the two Fama-French models (FF5 and FF6) and the HXZ4 model comes from the method by which the underlying portfolios used for the individual factors are constructed. While the Fama-French models use a 2x3 sort on size and one of the other factor characteristics at a time to construct factors, the HXZ4 model uses a 2x3x3 sort on size, investment, and profitability.

A.2. Transaction costs

To measure trading costs, we follow [Novy-Marx and Velikov \(2016\)](#) and use the effective bid-ask spread estimator from [Hasbrouck \(2009\)](#).¹¹ The costs are estimated using a Bayesian-Gibbs sampler on a generalized [Roll \(1984\)](#) model of stock price dynamics:

$$\begin{aligned}V_t &= V_{t-1} + \epsilon_t, \\P_t &= V_t + cQ_t,\end{aligned}\tag{2}$$

where V_t is the “efficient value” of a (log) stock price, P_t is the trade price, $Q_t = +1$ (-1) if the trade was a buy (sell), ϵ_t is a random public shock to the efficient value, and c is the effective one-way transaction cost. It follows from Eq. (2) that:

$$\Delta P_t = c\Delta Q_t + \epsilon_t,\tag{3}$$

¹¹This procedure is also used by a growing literature. See, e.g., [Detzel and Strauss \(2018\)](#); [Detzel et al. \(2019\)](#), [Novy-Marx and Velikov \(2019\)](#); [Chen and Velikov \(2019\)](#)

Hasbrouck estimates c via Bayesian methods applied to an augmented daily-frequency version of Eq. (3)¹²:

$$\Delta P_t = c\Delta Q_t + \beta r_{m,t} + \epsilon_t, \quad (4)$$

where $r_{m,t}$ denotes the market return on day t .

Hasbrouck (2009) documents that the effective spreads estimated using this procedure achieve a 96.5% correlation with the effective spread estimated using the Trade and Quote (TAQ) intraday data. While this measure does not account for the price impact of large trades, its estimation does not rely on intraday or proprietary data and is available for the full sample of publicly traded companies.¹³ The asset-pricing factors implicitly assume market orders because they transact at exactly the moment of closing. Thus, our net-of-costs factors can be interpreted as the net-of-costs return on the marginal dollar’s worth of investment in the literal factors. This is arguably the relevant correction for traders using the benchmark factors as a proxy for the opportunity cost of investing in a given LHS asset. However, this does not rule out that a small number of skilled (and non-representative) traders exist who can trade better versions of a given strategy, e.g., momentum.

The Hasbrouck procedure yields a number of missing observations that need to be filled in to compute trading-strategy costs. In each month t , we assign to each stock i missing an estimate of effective spread that of the stock j with the closest match in terms of market cap, and idiosyncratic volatility, which are the main observable determinants of transactions costs.¹⁴ Specifically, each month we rank all stocks’

¹²The Bayesian methods are necessary because Q_t is unobservable.

¹³For additional details on the trading cost estimation, see Hasbrouck (2009) and/or Novy-Marx and Velikov (2016). SAS code to estimate the effective bid-ask spreads is available on Joel Hasbrouck’s website at <http://pages.stern.nyu.edu/jhasbrou/>.

¹⁴See Novy-Marx and Velikov (2016) for more details. Idiosyncratic volatility is defined as the

market values and idiosyncratic volatilities, referring to the ranks as $rankME_i$, and $rankIVOL_i$, respectively. Then, we assign to stock i the estimated spread of the stock j with the smallest value of

$$\sqrt{(rankME_i - rankME_j)^2 + (rankIVOL_i - rankIVOL_j)^2}.$$

For each asset-pricing factor, f , we compute turnover (TO) and transaction costs (TC) as (e.g., DeMiguel et al., 2009; Kirby and Ostdiek, 2012):

$$TO_{long,t} = \frac{1}{2} \sum_{i=1}^{N_t} |w_{i,t} - \tilde{w}_{i,t-1}|, \text{ and} \quad (5)$$

$$TC_{long,t} = (1 + f_{long,t}) \sum_{i=1}^{N_t} |w_{i,t} - \tilde{w}_{i,t-1}| \cdot c_{i,t}, \quad (6)$$

where $c_{i,t}$ (r_{it}) is the one-way transaction cost (return) of stock i at time t , $N_t =$ number of stocks at time t , $w_{i,t}$ is the weight of stock i in the leg at time t after rebalancing, $\tilde{w}_{i,t-1} = \frac{w_{i,t-1}(1+r_{it})}{\sum_{j=1}^{N_t} w_{j,t-1}(1+r_{jt})}$ is the weight of stock i in the leg at time t before rebalancing, and $f_{long,t}$ denotes the return on the long leg of f . The transaction costs for the corresponding short leg ($TC_{Short,t}$) are defined similarly. The net-of-costs return on f (f_t^{net}) are:

$$f_t^{net} = f_t^{gross} - TC_{Long,t} - TC_{Short,t}, \quad (7)$$

where f_t^{gross} denotes the return ignoring costs. We estimate the w_{it} of the portfolios by replicating the factors following the respective studies (Specifically, [Asness and](#)

standard deviation of residuals from a CAPM based on the prior 90-days of a given stock's returns.

Frazzini, 2013; Fama and French, 2015, 2018; Hou et al., 2015). In doing so, we obtain necessary accounting data from COMPUSTAT and stock-market data from CRSP.

B. Full-sample simulation results

Table B.1: Bootstrapped net-of-costs maximum squared Sharpe ratios: Full-sample simulations

For each model we consider, the first column presents average net-of-costs maximum squared Sharpe ratios, $SR^2(f)$, from 100,000 simulation runs. Each run draws, with replacement, 552 random months from our sample period, January 1972 through December 2017. The six columns labeled by model names, ‘FF5’ to ‘FF6C’, present the percentage of bootstrap simulations in which the squared Sharpe ratio of the model defined by the row heading is greater than or equal to that of the model defined by the column heading. The last column, ‘Max’, presents the percentage of bootstrap simulation runs in which the model specified by the row heading has the highest squared Sharpe ratio among all models in the run.

	$SR^2(f)$	FF5	FF6	HXZ4	BS6	FF5 _C	FF6 _C	Max
FF5	0.96		5.4	93.4	64.0	0.0	0.0	0.0

HXZ4	0.70	6.6	1.0		0.0	0.1	0.0	0.0
BS6	0.90	36.0	13.3	100.0		1.5	0.2	0.2
FF5 _C	1.43	100.0	96.7	99.9	98.5		12.0	11.9
FF6 _C	1.51	100.0	100.0	100.0	99.8	100.0		99.8

C. Anomalies data and detailed results

C.1. Anomalies for LHS approach

For the left-hand-side (LHS) approach to model comparison discussed above, we need a set of test assets. To that end, we use the 120 anomaly signals from [Chen and Velikov \(2019\)](#).¹⁵ In contrast to [Chen and Velikov \(2019\)](#), which examines equal-weighted quintile strategies, we focus on strategies that sort stocks into deciles based on NYSE breakpoints and value-weight stocks within the long and short portfolios. This procedure more reliably produces significant net-of-costs returns. The anomalies are listed in [Table C.1](#).

The anomalies are constructed from the usual data sources. More than half of the predictors focus on Compustat data, and about 30% use purely price data. Most of the remainder use analyst forecasts, though several focus on institutional ownership data, trading volume, or specialized data. For further details, please see [Chen and Zimmerman \(2018\)](#).

¹⁵ These 120 anomalies come from the [Chen and Zimmerman \(2018\)](#) set of 156 cross-sectional return predictors from 115 publications in accounting, economics, and finance journals. [Chen and Velikov \(2019\)](#) remove 34 predictors that do not reliably produce decile sorts and 2 predictors they deem are due to risk to arrive at the final set of 120 anomalies. To the best of our knowledge, this is the most comprehensive set of net-of-cost anomaly returns.

D. Spanning tests after cost-mitigation

Table D.1: Spanning regressions using cost-mitigated factor models

Panel A of this table presents intercepts, with heteroskedasticity-robust t -statistics in brackets below, from regressions of the form: $MVE_{M0 \cup M1,t} = \alpha + \beta \cdot MVE_{M0,t} + \epsilon_t$, where MVE_{M0} and $MVE_{M0 \cup M1}$ denote the excess return on the ex-post mean-variance efficient portfolio consisting of the factors in models $M0$ and the union of $M0$ and $M1$, respectively. To measure the economic significance of the intercepts, Panel B presents squared Sharpe ratio improvements, $\% \Delta SR^2(M0, M1) = SR^2(M0, M1) / SR^2(M0) - 1$. The model ($M1$) is specified by the column heading, and the ($M0$) by the row heading. All models use the cost-mitigated versions of the factors defined in Section 5. The sample period is January 1972 to December 2017.
